Summary

NIAB has led the green pesticide trials as part of the BioBoost project in the UK. In order to ensure economic outcomes and continuity of the initiative beyond the scope and lifetime of the project, NIAB has worked very closely with several SME’s in their EAIH (Eastern Agritech Innovation Hub) incubator north of Cambridge to deliver positive data with great potential for commercial use. NIAB has also identified and collaborated with the commercial growers to carry out field-based trial work on behalf of BioBoost including the following commercial sites: Sunclose Farm, Simpsons Nurseries, Peter Beales Roses and Matthews Plants.

Organic by-products from crop and insect production were used to enhance the performance of biocontrol agents and commercially produced arbuscular mycorrhizal fungi (AMF). This inoculum was sourced from PlantWorks Ltd Kent UK. The following headline results were obtained:

- Incorporation of 10% v/v spent mushroom compost sustained an inoculum of entomopathogenic fungus in growing media resulting in improved control of vine weevil larvae
- Frass, when used as a potting material amendment repelled vine weevil and reduced egg laying in Heuchera plants.
- Fermented fruit waste liquor used as an attractant bait for spotted wing drosophila improved the control efficacy of low doses of insecticides.
- Amendment of peat-based growing medium with spent mushroom compost improved root colonisation with AMF and growth of Fatsia plants.

Ongoing current trials are investigating the effects of organic amendments and AM fungi on the growth and flowering of roses.
1. Control of soil-dwelling insect pests using chitinous wastes and entomopathogenic fungi

Chitin is a polysaccharide and a primary component of arthropod exoskeletons and fungal cell walls. Plants growing in soil or potting compost detect chitin by plant chitosan receptors, therefore plants perceive the presence of chitin as potential signs of invertebrate pest attack. This causes plants to up-regulate their defence mechanisms, which can include production of thicker leaf cuticles and release of chitinases and metabolites into the soil. Chitin can also provide entomopathogenic fungi (EPF) with an alternative nutrient source; these fungi kill insects present in soil or growing media. Sources of these feedstocks are available as by-products from black soldier fly larvae production (frass, @14% chitin) and spent mushroom compost (SMC, @5% chitin). See Figures 1 a and b.

In BioBoost, we have used these by-product feedstocks in crop pest control (1) as a nutrient source for entomopathogenic fungi (EPF) which can be used as a bio-control agent when they attack soil-dwelling pests (2) by systemic uptake by plants making them unpalatable to pests and (3) through a pest repellent effect when used as an amendment in potting material. The target pests in this work have been western flower thrips (WFT) (*Frankliniella occidentalis*) which are foliar pests that pupate in the growing medium, and black vine weevil (*Otiorhynchus sulcatus*), the larvae of which attack the roots of plants.

![Fig. 1](https://www.BioBoosteurope.com/)

### 1.1. Chitinous wastes as a nutrient source for entomopathogenic fungi

Commercial growers are concerned that entomopathogenic fungi (EPF) are not currently as effective as chemical pesticides; but are keen to find an alternative as these chemical options become less acceptable in fresh produce. Incorporating SMC into a peat based potting medium has been shown to increase the efficacy of the commercial formulation of the entomopathogen *Metarhizium anisopliae* Met52, against vine weevils in experiments on strawberry plants. In BioBoost, we tested this technique against western flower thrips WFT, in a coir-based growing medium, and subsequently in our pilot study on a commercial scale nurseries horticultural stock and fruit crops.

#### 1.1.1. Control of western flower thrips

Preliminary tests showed that although *M. anisopliae* Met52 colonised sterile frass, it did not colonise pasteurised frass. Further experiments were therefore conducted using SMC (Fig. 1c). A small-scale experiment was undertaken to test the effect of coir growing medium applied SMC + EPF treatments on pupae of WFT and subsequent population levels of adults.
The treatments added to wetted coir were as follows:

(a) No treatment, control  
(b) SMC 10% v/v  
(c) SMC 10% v/v + Met52 0.05 g/l  
(d) Met52 0.5 g/l  
(e) SMC 10% v/v + Met52 0.05 g/l

The coir-based compost and the different amendments were well mixed and then dispensed into small plant pots 7 x 7 x 8 cm. Each pot was enclosed in a plastic box to prevent losses of WFT and to prevent cross contamination among treatments. A piece of green bean pod was placed on the surface of the growing medium in each pot as a food source for WFT. There were 5 replicates of each treatment. Pots were held at 20°C for one week prior to infestation with WFT. Late instar WFT larvae (20) were introduced on to the bean pod in each box and the pots were returned to 20°C 14L:10D conditions.

The adults that had emerged from larvae that had pupated in the compost were recorded; bean pods and the outside of the pots plus the inside of the boxes were inspected under a stereo microscope. Any adults found were removed on each recording occasion. Populations of Metarhizium anisopliae (as colony forming units; cfu) present in the growing medium were assessed before inoculation of the plants and at intervals during the experiment.

No Metarhizium was detected in the coir control and 10% SMC treatments. The population of Metarhizium in the Met52 inoculated coir declined during the experiment (Fig.3a). The addition of 10% SMC and Met52 to the coir resulted in a sustained population of Metarhizium for over 60 days.

There was a trend for the combined SMC + Met52 treatments to produce the fewest WFT adults, although the difference between treatments was not statistically significant (Fig.3b).

Fig. 3 (a) Population of Metarhizium in coir and (b) emergence of adult thrips in different SMC and Met52 treatments.
1.1.2. Control of black vine weevil on a commercial nursery

Following the preliminary lab-based trials the experiment was then up-scaled at commercial nursery sites. A trial was set up at a commercial nursery (Matthews Plants, Roydon, Essex) to compare the efficacy of the combined SMC + EPF treatment against the individual SMC or EPF treatments for control of black vine weevil in ornamental nursery stock. Heuchera was chosen as a test species since it is highly susceptible to vine weevil attack. Live healthy vine weevil larvae (3) were introduced into some of the pots.

In addition to the inoculated treatments, an area of known natural infestation of vine weevil on the nursery was used to determine whether differences in vine weevil source would impact on the treatment.

The following treatments and/or vine weevil larvae were added to a peat based growing medium (Sinclair Professional):

- (a) No treatment, control
- (b) Control + vine weevil
- (c) 10% SMC
- (d) 10% SMC + vine weevil
- (e) Met52, 0.5g/l
- (f) Met52, 0.5 g/l + vine weevil
- (g) 10% SMC + 0.5g/L Met52
- (h) 10% SMC + 0.5g/L Met 52 + vine weevil

There were 15 replicate pots of each treatment and 30 replicates of the controls (a and b) (Fig. 4 a and b). The experiment was set up in July 2017 and assessed for live and dead vine weevil larvae in March 2018 (Fig. 4c). Samples of growing medium were taken at intervals and assessed for *Metarhizium* populations.

No *Metarhizium* was detected in the unamended peat or 10% SMC treatments. Where *Metarhizium* was added without SMC, there was a gradual decline in the *Metarhizium* population in the growing medium and it could not be detected after 35 days (Fig. 5a). The addition of 10% SMC with Met52 resulted in a sustained *Metarhizium* population in the growing medium and a reduction in the number of live vine weevil larvae.
1.1.3. Control of black vine weevil in raspberry

A second pilot trial was set up at Sunclose Farm, Milton, Cambridgeshire to investigate the use of SMC+Met52 and frass for control of black vine weevil. The following treatments have been applied to each of 20 pots of raspberries grown coir in 10 litre pots:

(a) No treatment, control  
(b) 10% v/v frass  
(c) 10% SMC + 0.05g/l Met52.

The experiment was set up in May 2019 and will be assessed in November 2019.

1.2. Chitinous wastes as a pest repellent materials

In the second part of the NIAB pilot, we are investigating the use of chitinous wastes and other organic amendments as potting materials to repel the activities of egg-laying vine weevil adults. This is an additional treatment where the initial activities of the adult are impacted, rather than treating the destructive larvae once they have been introduced to the host plant.
1.2.1. Comparison of potting materials for Heuchera

An experiment with Heuchera grown in peat and bark medium (Levington) was set up in August 2018 with the following potting material treatments:

(a) Control, peat and bark medium  
(b) AgriGrub frass  
(c) Celsius, Zee No Weevil, an olive industry by-product.

The potting materials amendments were applied as a 1 cm layer to Heuchera planted in 1.5 litre pots. The pots were set out with Euonymus plants, which were heavily infested with vine weevil adults and left outside for two months, where the adults were free to move from pot to pot. In October 2018, the pots were brought into an unheated glasshouse and assessed for vine weevil larvae in February 2019. The fresh weight of plants with and without larvae at the end of the experiment was also determined.

![Fig. 7](a) Potting material experiment and (b) vine weevil larvae in Heuchera pot.

The frass potting material resulted in significantly fewer vine weevil larvae per pot than both the control and olive by-product (Fig. 8a). The olive by-product had significantly fewer larvae than the control. The frass potting material resulted in a small reduction in Heuchera plant weight in uninfected pots (Fig. 8b).

![Fig. 8](a) Vine weevil larvae per pot and (b) Heuchera plant fresh weight at the end of the experiment.

1.2.2. Comparison of potting materials for red robin shrub (Photinia)

An experiment was set up at Simpsons Nurseries, Fordham, Cambridgeshire to compare chitinous wastes as potting materials for vine weevil control. The experiment was set up in May 2019 with the following treatments:

(a) Coarse bark, control  
(b) Frass  
(c) 10% SMC + 0.05g/l Met52.
The potting materials were applied as a 1 cm deep mulch. The pots will be assessed for vine weevil larvae in November 2019.

*Fig. 9 Potting materials at Simpsons Nurseries to compare repellent effect on vine weevils.*
2. Improving the establishment of arbuscular mycorrhizal fungi with chitinous wastes

Arbuscular mycorrhizal fungi (AMF) form a mutually beneficial association with plant roots; enabling the plant to benefit from the fungus ability to access nutrients from the soil. AMF colonised plants have been shown to suffer from reduced pathogenic attack and from better water use efficiency; hence, they can also improve plant tolerance to drought and enhance plant growth. The work in BioBoost has aimed to determine whether the addition of a chitinous waste to the soil or growing medium can improve the beneficial colonisation of plants by AMF and whether this improves plant growth.

2.1. Effect of arbuscular mycorrhizal fungi and spent mushroom compost on the growth of Fatsia

A trial was set up at a commercial nursery (Matthews Plants, Roydon, Essex) to compare the efficacy of the combined SMC + AMF treatment with the individual SMC and AMF treatments for establishment of AMF and plant growth. AMF inoculum was provided by Plantworks Ltd, Sittingbourne, Kent.

The following treatments were set up in 3 litre pots containing a peat-based growing medium (Sinclair professional):

(a) No treatment, control
(b) 10% SMC
(c) 30 ml AMF inoculum in planting hole
(d) 10% SMC in growing medium, 30 ml AMF inoculum in planting hole.

The experiment was set up in July 2017 and assessed in March 2018 for AMF in the growing medium and for plant growth.

The addition of SMC or AMF inoculum alone did not result in a significant increase in the percentage of roots colonised with AMF (Fig. 10). The combined SMC + AMF treatment resulted in a significantly higher percentage of AMF colonised roots and in greater plant weight than the control or individual SMC or AMF treatments (Fig. 11).

![Fig. 10 Percentage of Fatsia roots colonised with arbuscular mycorrhizal fungi](https://www.BioBoosteurope.com/Interim Report Pilot Green Pesticides)
2.2. Effect of arbuscular mycorrhizal fungi and spent mushroom compost on the growth of pot roses

An experiment was set up at NIAB Innovation Farm in April to determine the effects of AMF inoculum and spent mushroom compost on the growth and AMF root colonisation of pot grown roses. Bare root hybrid tea rose (cv Ruby Wedding) and dog rose (*Rosa canina*) plants were potted in 10 litre pots containing a peat+bark growing medium (Levington) with the following amendment treatments:

(a) No treatment, control  
(b) AMF inoculum, 40 ml per pot  
(c) 10% v/v Spent mushroom compost  
(d) 10% v/v Spent mushroom compost + AMF, 40 ml per pot.

Replicate pots (16) of each treatment were prepared. The plants were grown on Mypex matting with drip irrigation (Fig. 12). Plants were assessed for height and number of shoots and flowers in July 2018 and November 2018. Samples of root/growing media were taken for AMF measurement in July and at the end of growing season in November 2018.

The addition of AMF inoculum to the pots resulted in a measurable level of root colonisation when assessed in November 2018 and January 2019. The addition of SMC had no significant effect on the percentage of roots colonised with AMF (Table 1). There were no significant differences in flowering or growth between the treatments. This may have been due to the optimised irrigation and nutrition.
given to the pots; which tends to reduce rates of colonisation if plants have access to sufficient nutrients. The hybrid tea roses were used for the soil plot experiment (see below). The dog roses will be assessed again in June 2019.

### 2.3. Effect of arbuscular mycorrhizal fungi and spent mushroom compost on the growth of roses in soil

An experiment was set up with Peter Beales Roses Ltd, Attleborough, Norfolk to determine the effects of SMC and AMF on the growth of roses in soil. Potted hybrid tea roses (cv. Ruby Wedding) and bare root floribunda roses (cv. Queen Elizabeth) were planted into soil plots. The plots were planted in February and will be assessed for plant growth and soil AMF populations during the summer and autumn of 2019.

*Fig. 13* Roses planted into soil plots at Peter Beales Roses, Norfolk.
3. Use of fruit waste liquor as a bait attractant for spotted wing drosophila

Spotted wing drosophila (*Drosophila suzukii*) (SWD) is a major pest of fruit crops. Soft fruit growing produces around 5 tonnes of waste fruit per hectare (Fig. 14). Without treatment, this becomes a potential source of infestation for subsequent crops. The waste fruit is being fermented in sealed pallet bins to destroy any larvae of the pest that may be present in the waste. The fermented liquor is attractive to SWD and can be used as an attractant bait. Experiments in BioBoost are investigating the use of the bait in combination with low, sub-lethal concentrations of insecticides in an ‘attract and kill’ control strategy.

![Image of fruits](https://www.BioBoosteurope.com/)

*Fig. 14 Soft and stone fruit wastes – about 15-20% of the harvested crop.*

3.1. Production of an attractant bait for SWD control from fruit waste liquor

Fruit waste consisted of soft fruit (strawberries or raspberries) or stone fruit (plums or cherries), kept at ambient temperatures (12–19 °C) for up to two days or at 4 °C for up to 10 days from harvesting. The majority of the fruit was undamaged but classed as unmarketable due to over- or under-size, uneven shape or ripening, or blemishes; less than 5% of the fruit in any of the batches was mechanically damaged or rotting.

Fruit waste was inserted into 615 litre pallet boxes (460 kg soft fruit or 410 kg stone fruit) to within 100 mm of the top. The pallet boxes were then sealed with a single layer of polyethylene stretch shrink wrap, with an additional covering of a plastic lid. The lids were then sealed on to the pallet boxes around the rim with a further layer of shrink wrap. Once the bins were sealed, rapid depletion of oxygen and an increase in carbon dioxide concentration occurred due to the fermentation of the fruit, this resulted in death of the eggs, larvae, pupae and adults of SWD.

After 10 days, the fermented waste separated into solid and liquid fractions, which is then filtered and can be used as a bait for the SWD adults. This method is now used commercially on several farms including Langdon Manor Farm, Faversham Kent (Fig.15).
3.2. Testing of waste fruit liquor as a SWD bait attractant

A jar bioassay was used to test the effect of baits and different insecticides at sub-lethal concentrations on *D. suzukii* mortality. Baits and/or insecticides were pipetted as droplets on to blackberry leaves in the jars which contained 12 SWD adults (Fig. 16). The following bait treatments were compared:

(a) Water control  
(b) Fruit strawberry juice waste liquor (FSJ)  
(c) Yeast, *Hanseniaspora uvarum*  
(d) Yeast, *H. uvarum* + FSJ  
(e) Combi-protec, a commercial SWD bait.

The above baits were used in combination with insecticides at dilute doses: spinosad, cyantraniliprole, thiacloprid, lambda-cyhalothrin and water (control). After 3 days, the jars were assessed for SWD mortality.

Without baits, the dilute doses of insecticides were ineffective in killing SWD, with similar numbers of live SWD to the water control after 3 days (Fig. 17). All of the bait treatments were effective in increasing the SWD toxicity of the insecticides. There were no significant differences in efficacy between the different bait treatments, including fermented waste strawberry juice.
Fig. 17. Effect of bait and insecticide treatments on mortality of spotted wing drosophila

A commercial scale trial with fruit waste as a SWD bait is now being set up at Sunclose Farm, Milton, Cambridgeshire. The results will be available later in 2019.
4. Future work in BioBoost on green pesticides

In 2019, commercial-scale trials in the 2SeasInterreg Region will concentrate on the further development of the following treatments:

- A growth promoting fertiliser for roses
- Control of vine weevil in nursery stock and fruit crops using chitinous wastes, as potting material and/or in conjunction with entomopathogenic fungi
- Large-scale tests with waste fruit liquor in ‘attract and kill’ control of spotted wing drosophila
- Use of chitinous wastes for the production of arbuscular Mycorrhizal inoculum (in association with PlantWorks Ltd Kent).

Reports from these findings will be detailed in the next project report. A report on the views and perception of the commercial growers will also be collected and potential for use as a commercial aid in the future.
